MULTIMODAL IMAGING IN PATIENTS WITH MULTIFOCAL CHOROIDITIS WITH OUTER RETINAL/CHORIOCAPILLARIS-BASED PATHOLOGY

Sonja Cekić1, Predrag Jovanović1,2, Ivan Jovanović2, Gordana Stanković-Babić1, Dijana Risimić3

The purpose of this study was to present different multimodal imaging technics in patients with multifocal choroiditis, punctate inner choroidopathy (PIC), birdshot chorioretinitis (BCR), acute posterior multifocal placid pigment epitheliopathy (AMPPE), multiple evanescent white dot syndrome (MEWDS) and serpinginous choroiditis (SPC) and to estimate their diagnostic and prognostic value.

The study was performed at the Clinic for Eye Disease, Clinical Centre Niš, Serbia. During the period of six years, ten patients with diagnosed multifocal chorioretinitis were examined. Standard ophthalmological examination in all patients included: visual acuity evaluation, slit lamp biomicroscopy, applanation tonometry, indirect ophthalmoscopy, photodocumentation and fluorescein angiography, optical coherence tomography (OCT) and ultrasonography in indicated cases. Standard laboratory examination, immunological examination and HLA typing were performed as well.

Visual acuity was well preserved in all cases except in SPC. The disease was bilateral, in cases of SPC, AMPPE and PIC, and recurrence was present in cases of BCR and PIC. SPC and PIC were characterized by chronic evolution.

The common features of all presented cases of multifocal choroiditis entities were: minimal lesions at the initial stage of disease, multifocal or white yellow multiple lesions, during the progression of disease and consequent degeneration of retinal tissue and choroid proven by OCT and FA.

OCT is important for diagnose, differential diagnose and follow-up.

The obtained results are comparable with the existing studies that follow individual response variability, which has not yet been fully elucidated.

Key words: chorioretinitis, diagnosis, imaging

Introduction

Multifocal chorioretinitis presents a group of rare disorders which primary pathologic process occurs at or near the level of retinal pigment epithelium (RPE) with or without photoreceptor outer segment and choriocapillaris involvement (1, 2, 3). The pathophysiology presumes either vasculitic obstruction of the choriocapillaris with secondary infarction of the overlying RPE or, possible, immunologic response on RPE itself (5, 6, 7). Many clinical features of these individual entities overlap, causing confusion (8, 9).

The aim of this study was to present different multimodal imaging technics such as, color fundus photography (FF), fluorescein angiography (FA), high definition ocular tomography HD OCT, ultrasonography in patients with multifocal choroiditis with outer retinal/choroidal based pathology-punctate inner choriocapillaropathy (PIC), birdshot chorioretinopathy (BCR), acute posterior multifocal placid pigment epitheliopathy (AMPPE), multiple evanescent white dot syndrome (MEWDS) and serpinginous choroiditis (SPC) and to estimate their diagnostic and prognostic value.
Materials and methods

During the period of six years, ten patients were diagnosed with multifocal choroiditis at the Clinic for Eye Disease, Clinical Center Niš. All patients gave standard written consent for all diagnostic procedures before the examination. Standard ophthalmological examination was performed in all patients: visual acuity, slit lamp biomicroscopy, applanation tonometry, indirect ophthalmoscopy, photodocumentation and fluorescein angiography (FA) (Carl Zeiss Digital Fundus Camera Visucam Lite), high definition, standard domain, optical coherence tomography (SD OCT Cirrus and RTVue 100) and ultrasonography B scan (USG Tomey) in indicated cases. The imaging methods, FA and SD OCT were done at the same condition and repeated during the treatment of disease. Standard laboratory examination, immunological examination and HLA typing were performed as well.

Results

Of 20 eyes examined during our study, 6 were diagnosed with AMPPE, 2 MEWDS, 4 PIC, 4 SCP and 1 BCR. Clinical and multimodal imaging results of examined patients are presented in Table 1, and Figures 1 to 6.

In case with PIC, acute lesions appeared as nodular collections under the retinal pigment epithelium, and presented as solid inflammatory retinal pigment detachment (PED) on OCT (Figure 1). These solid PED appeared to be ruptured leading to inflammatory infiltration of the subretinal space and outer retina, often with a widespread loss of the outer retinal architecture beyond the area of the inflammatory exudate. During the treatment with corticosteroids, in patients with PIC, rapid regression of PED was noted, with a slower resolution of the abnormalities of outer retinal architecture. FA revealed more lesions that appeared as early hyperfluorescent lesions and late staining (Figure 1).

Anterior segment examination presented with mild inflammation, and mild vitritis in patients with BCR (Figure 2) (Table 1). On OCT focal disruption of the photoreceptors, inner and outer (IS/OS) focal or generalized were present (Figure 3). In macula, cystoid macular edema could be diagnosed. FA revealed prolonged arteriovenous transit time, optic disc hyperfluorescence, and vascular leaking (Figure 3). The delay of transit time is a phenomenon known as "quenching" and is pathognomonic for BCR.

Diagnosis of AMPPE was established in 3 patients and clinical signs were present in both eyes in different stages of disease (Table 1). On OCT hyperreflectivity of the outer retinal layers, inflammatory PED with presence of inflammatory cells were present (Figure 4). As the lesions resolved, hyperreflectivity of outer layer decreased. The IS/OS disruption, and atrophy of RPE can persist (Figure 4). FA demonstrated lesions with early hyperfluorescence followed by the subsequent hyperfluorescence in the late venous phase (Figure 4).

Accumulation of hyperreflective material that rested on RPE, and extended through the interdigital zone, ellipsoid zone, and outer nuclear layer (ONL) was observed by OCT in patients with MEWDS (Figure 5). The abnormalities of retinal architecture restored spontaneously. During FA in these patients, multiple lesions with early hyperfluorescence in a wreath-like configuration were detected. The lesions were presented in mid retina and hyperfluorescence persisted in late phase of FA (Figure 5).

During the active phase in patients with SPC, hyperreflective lesions and thickening of the outer retina were noted (Figure 6). Hyperreflective inflammatory PED, similar to PIC, was present as well (Figure 6). The reflectance of choroid was increased causing the so called waterfall effect (Figure 6). The inner and outer photoreceptor layers as well as their junction were interrupted. Active lesions on FA showed early hypofluorescence and late hyperfluorescence of the border (Figure 6). Old lesions were presented by window defect and late staining on FA (Figure 6).

**Discussion**

Multifocal chorioretinitis presents separate group of posterior uveitis with similar clinical findings. Multimodal imaging such as color photofundus, FA, OCT, and ultrasonography can help in diagnosis, differential diagnosis and follow-up of disease course (10, 11, 12, 13). Authors also proposed fundus autofluorescence (FAF) and angio OCT as methods of choice for diagnosis and follow-up of MPC (13).

Anterior segment inflammation was present in patients with SPC. In our patient, in the color photography, findings differed in size, color or localization of lesions (Table 1). Atrophic lesions were present in patients with BRC and SPC; pigmented lesions were present in patients with AMPPE. Similar results are present in the literature (1, 7, 14, 15, 16). Retinal architecture restored spontaneously in patients with MEWDS. BRC, SPC and PIC had a chronic course. These entities need to be monitored closely in order to detect the development of choroidal neovascularization (CNV) (13). During our study, we did
not notice CNV in patients. New imaging technic, angio OCT, is more sensitive in detection of CNV (13).

Imaging technics are important in differential diagnosis of MPC for infectious uveitis as well as for primary or secondary neoplastic changes (6, 7, 16).

Limitations of FA imaging are opacification of anterior segment intensive vitreous haze or hemorrhage in vitreous. It is an invasive method of examination, and practitioner should be cautious about patients with allergic reactions, heart, liver and kidney disease.

OCT examination is easy to perform and non-invasive method. However, some limitations of OCT examination are present. Corneal opacification, dense cataract, significant vitreous haze or hemorrhage in the eyes are limiting factors for OCT examination. Eye tracking system overcomes acquisition errors and enables a high intra-observer reproducibility allowing determination of minimal changes that may occur between successive examinations (7). Shading of the underlying retinal structures by hyper-reflective lesions such as exudates, hemorrhages and major retinal vessels can lead to the loss of detail of underlying morphology.

Conclusion

Multimodal imaging has allowed us to better understand morphology, activity and stage of lesions. The common features of all presented cases of multifocal choroiditis entities are: minimal lesions at the initial stage of disease, multifocal white, or white/yellow multiple lesions, during the progression of disease degeneration of retinal tissue and choroid confirmed by OCT and FA, similar clinical presentation. OCT is important in diagnosis, differential diagnosis and follow-up.

Cilj naše studije je prikaz različitih tehnika vizuelnog prikaza bolesnika sa multifokalnim horoiditism i to: punktiformnom unutrašnjom horoidopatijom (PIC), Birdshot horioretnopatijom (BRC), akutnom multifokalnom pigmentom plakoidnom epiteliopatijom (AMPPE), sindromom multispilnestajućih belih tačkica (MEWDS) i serpenginoznim horoiditisom (SPC); i utvrditi njihov dijagnostički prognostički značaj.

Studija je sprovedena na Klinici za očne bolesti Kliničkog Centra u Nišu. U periodu od šest godina kod deset bolesnika postavljena je dijagnoza multifokalnog horioretinitisa. Standardni oftalmološki pregled podrazumevao je: određivanje subjektivne vidne oštrine, pregled prednjeg segmenta biomikroskopom, aplanacionu tonometriju, indirektnu oftalmoskopiju, fotodokumentaciju, fluresceinsku angiografiju (FA), optičku koherentnu tomografiju (OCT) i pregled ultrazvukom. Sprovedeno je i standardno laboratorijsko ispitivanje, imunološko ispitivanje i sprovedena je HLA tipizacija.

Vidna oštrina bila je očuvana kod svih bolesnika osim kod pacijenta sa dijagnozom SPC. Bolest je bila bilateralna kod bolesnika sa AMPPE, SPC i PIC. Hronični tok bolesti bio je prisutan kod bolesnika sa dijagnozom SPC i PIC.

Zajedničke karakteristike kod svih bolesnika sa multifokalnim horoiditom bile su: minimalna oštećenja u početnom stadijumu bolesti, brojne beličaste ili žutobeličaste lezije, kao i to da napredovanje oboljenja dolazi od degenerativnog oštećenja tkiva. Promene su dokazane OCT i FA metodom.

OCT je značajan za diferencijalnu dijagnozu i praćenje. Dobijeni rezultati u skladu su sa rezultatima sprovedenih studija, a različitost nalaza u pojedinim oboljenjima predmet je daljeg istraživanja.

Ključne reči: horioretinitis, dijagnoza, vizuelni prikaz
